ABSTRACT

The purpose of this research was to test for potential antagonist-mediated effects of orb-web building spiders (*Argiope aurantia*) on the pollinator visitation rate due to the presence of an orb-web building spider on the visitation time of pollinating insects to the Orange Coneflower (*Rudbeckia fulgida*). Orb-web building spiders have not been thoroughly studied in predator-pollinator-plant systems, and understanding their role may shed some light on the ecology of multi-species interactions. To test for indirect effects of orb-web building spiders on insect visitation to plants, a small-scale manipulative experiment was conducted at a 6x6m, off-road, grassy patch during August of 2007 about 30 meters northeast of the University of Akron Field Station at the Bath Nature Preserve (41° 10'53" N; 81° 39'05" W) in Bath, OH. Pollinator visitation to evenly spaced *R. fulgida* plants was recorded on 11 weather-permitting days during the hours of 0900 and 1600. Three replicates of three treatments groups (spider with web, web, and control) were set up in mesh covered hardware cloth frames, and each frame with the associated treatment was randomly assigned next to individual potted plants. A univariate ANOVA did not support the effect of the presence of *A. aurantia* on pollinators' visitation time to *R. fulgida*. The inconclusive results could indicate a lack of treatment effects due to the design of the experiment, and/or the ecology of the system.

VI. RESULTS.....	24
Descriptive data.....	24
Visitation time analysis.....	24
Power analysis.....	30
VII. DISCUSSION.....	32
Pollinator visitation across days.....	33
Pollinator visitation across time-points.....	33
Pollinator visitation across all 5-minute observations.....	33
Summary of findings.....	34
Ecological explanations.....	34
Experimental design limitations.....	39
Suggested future study.....	52
VIII. CONCLUSIONS.....	53

CHAPTER I

INTRODUCTION

Multi-species interactions:

Interactions between three or more trophic levels have not been as thoroughly studied as two level systems, yet may be important for the evolution and ecology of ecological communities (Strauss and Irwin 2004). These complex interactions across trophic groups are commonly known as multi-trophic or multi-species interactions (Tschamntke and Hawkins 2002) and will hereafter be referred to as multi-species interactions. Multi-species interactions may include both below and aboveground constituents in terrestrial (Schmitz et al. 2000), aquatic (Hill and Lodge 1995), and mixed systems (Knight et al. 2005a). The consideration of multi-species interactions may have implications for biological control in agricultural systems (Tschamntke and Hawkins 2002). The knowledge of multi-species interactions is limited for both agricultural systems and natural systems; empirical studies examining interactions at multiple functional levels are needed to understand the complexities of these systems (Tschamntke and Hawkins 2002).

Top-down ecology:

One specific type of multi-species interaction is a top-down interaction (Tschamntke and Hawkins 2002). Hairston, Smith, and Slobodkin (1960) mentioned the

idea of the top-down regulation of populations at lower trophic levels by predation from higher levels. Their paper discussed how predators might be regulating plant populations through the reduction of herbivore populations (Hairston et al. 1960). A classic top-down example found sea urchin populations to decline due to predation by sea otters, triggering a dramatic increase in the diversity and biomass of sea kelp (Duggins 1980). The increase was attributed to sea otters regulating populations of urchins that over-grazed the kelp beds in the absence of predators (Duggins 1980). Since the introduction of this idea, top-down effects have been found in a multitude of systems, including aquatic (Hill and Lodge 1995) terrestrial (Schmitz et al. 2000, Pace et al. 1999), and mixed aquatic and terrestrial systems (Knight et al. 2005a). It should be kept in mind that “top-down” ecology generally encompasses trophic-centered, population-level dynamics in a unidirectional cascade down trophic levels, but may include behavioral dynamics as well (Reader et al. 2006). Furthermore, top-down effects are not thought to be prominent in all ecological systems (Strong 1992) such as complex forest ecosystems (Gruner 2004), but may play an important role in community-level ecology through predation effects on mutualists, which may limit plant reproduction such as seed output (Knight et al. 2005a).

It should be known that examples of bottom-up effects have been found, but certain types of effects such as trait-mediated indirect effects have not been thoroughly studied in these systems (Werner and Peacor 2003). Bottom-up effects can be characterized as the effects of plant-centered traits and ecosystem qualities that may affect the population dynamics at higher trophic levels (White 1978, from Knight et al. 2006). Some of these density and population altering effects have been attributed to plant

resource limitations, chemical compounds that may deter herbivores from grazing, and active responses of prey such as predator avoidance (see Power 1992, White 1978).

Top-down versus bottom-up regulation of populations is debated, but both types of effects have been found to be significant (Hunter et al. 1997, Gripenberg and Roslin 2007). A suggested shift in paradigm moves from searching for the presence of an effect to quantifying the magnitude of these effects in trophic webs (Hunter and Price 1992) while taking spatial context into account (Gripenberg and Roslin 2007).

The type of pollinator was recorded to Order as best as possible. The marks recorded for pollinators were: Small, black bee (possibly *Ceratina* or *Lasioglossum*), other Hymenoptera (possibly Halictidae), Bumblebee (Apidae), Lepidoptera (possibly Nymphalidae or Hesperiiidae), and Diptera (Syrphidae). Syrphid flies were initially tallied as Hymenoptera but were corrected to Diptera upon realization of the error. Insect lengths were not measured, but based on visual observation the small black bees and other Hymenoptera categories mostly consisted of small pollinators under 1 cm long.

probability of making an incorrect assertion of no effect. Therefore, the test was concluded to be inconclusive rather than accepting the null hypothesis (Toft and Shea 1983).
